INHALER VALVE MECHANISM

This invention relates to inhalers for medicaments or the like and more particularly to inhaler valves.

5 Inhalers typically consist of a storage container and a metering valve assembly. In the valve assembly a metering volume is provided between two valves. The sequence of operation of the valve assembly generally employed is as follows. When the device is not in use a dose of medicament is stored in the metering volume and the outermost of the two valves is maintained closed. The inner valve is open at this time allowing fluid
10 communication between the metering volume and the contents of the storage container. When a dose is to be dispensed, the inner valve is first closed immediately prior to the outer valve opening. In this way when the contents of the metering volume are discharged, the escape of the medicament stored in the container is prevented. Dispensing is generally achieved by the container being depressed within a housing,
15 either directly by the action of the user or by means of an operating mechanism. When the medicament has been dispensed, the valve sequence reverses as the container is allowed to return to its original position and state: thus the outer valve closes prior to the inner valve opening and the metering volume refills with medicament from the container. The inhaler is left in this state until it is required again for use.

20 Such a dispensing cycle is a necessary feature particularly of manually operated conventional devices, since the dose retained in the metering volume during the storage has to be dispensed immediately on demand.

Breath actuated devices currently on the market retain this valve technology, but in general operate by loading a spring prior to inhalation by means of some user action
25 such as opening a mouthpiece cover. This stored energy is then released automatically, to depress the pressurised container within the housing, as the patient inhales.

The advantage of breath actuated inhalers is that they eliminate the need to coordinate the press and breathe actions of manually actuated inhalers. As a result of this the deposition levels of the drug in the lung are not dependent on the user's coordination
30 skills. However, the high force required to fire the canister gives rise to production design compromises. Firstly, the size of the device: to fire the canister typically requires a large spring to be fitted into the design; this can be problematic as users prefer small discrete devices. Furthermore, the large firing force must be released by the small force available from the patient's inhalation. To achieve this requires a mechanism that gives a high
35 gearing of the breath force, typically 500:1. This generally has to be achieved by a multi-stage mechanism with several components resulting in a relatively complex mechanism.

A breath operated inhaler that uses the present canister valve mechanism could be of much simpler design because it is not necessary to have a source of stored energy, for example, a large spring, to release the dose.

Generally there is a desire to make inhalers as small and discrete as possible.

- 5 The necessity for a high force spring in the device means that small, thin walled components must endure high stress levels. This often requires more costly, high performance polymers to be used. The problem is particularly acute in devices with dose counting. Such devices typically require that an electrical switch is actuated, or mechanical counting mechanism is indexed at the point in the stroke where the canister
10 releases its dose. To avoid the danger of counting errors the counting and dose release should ideally occur at the same point in the canister stroke. For highly stressed materials, displacement due to creep can mean that the point at which dose counting occurs drifts over the life of the device making counting errors more likely.

- In conventional canister valves a dose is delivered into the metering chamber
15 immediately after the previous dose is released. The canister is stored with the metering chamber full and the dose must be contained therein for the time between taking one dose and the next. Inhalers, in general, whether manually or breath operated, suffer from the problem that the dose in the metering chamber can diminish over time either by escaping through the seals of the outer valve or by flowing back into the storage container if the
20 canister is stored inverted. If the metered dose in the metering chamber leaks away, it will not refill even if the canister is subsequently stored upright. The reduction in the dose in the metering chamber then causes the user to receive a lower than expected dose at next usage.

- According to the present invention there is provided a valve mechanism for use
25 in an inhaler comprising a pressurised container and a metering chamber, the valve mechanism comprising:

- a first valve member arranged to be positioned between the pressurised container and the metering chamber, the first valve member being movable between a closed position in which the container is closed, and an open position in which the container is
30 open to the metering chamber, the first valve member being biased to remain in the first position by the pressure in the container and a return spring; and

- a second valve member movable between a rest position in which the metering chamber is closed, a metering position in which the valve member actuates the opening of the first valve member to enable a metered dose of medicament to be dispensed into
35 the metering chamber, and an open position in which the metering chamber is open to allow medicament to be inhaled.

Preferably, the second valve member includes a surface that enables the pressure in the metering chamber to assist the opening of the second valve member.

The surface at the end of the second valve member that contacts the first valve member during metering of a dose, may be a cam surface or a stepped surface and the first valve member has a cooperating surface.

The second valve member may be a radial seal, and wherein the movements of the first and second valve members may be independent of one another.

Preferably, the end surface of the second valve member allows the size of the dose to be adjusted.

The dose size may be variable and may be user defined.

The cross-section of the first valve member may be T-shaped.

A valve mechanism according to the present invention may be incorporated in an inhaler device.

The operating sequence of a valve according to the present invention ensures that the dose is metered just before delivery and so resides in the metering chamber for only a very short time. Therefore the device is stored with the metering chamber empty. Thus the problems of reduction of the metered dose seen with conventional valves are eliminated.

Another advantage of the valve of the present invention is that the force required to release a dose or the "force to fire" can be very small. This is achieved by dissociating the metering and firing actions and by using the pressure of the fluid to assist the firing action.

A further advantage of the valve of the present invention is that the force to meter a dose can be much lower than for a conventional valve. Conventional devices have radial seals as both the inner and outer seals. However, with the present valve only the outer seal needs to be a radial seal. The frictional losses of a face seal are extremely small in comparison with those of a radial seal and this means that a weaker return spring can be used to keep the inner valve closed than is required in a conventional device with radial seals for both the inner and outer valves. The combined effect of reduced frictional losses at the seals and a weaker inner valve return spring allows the valve of the present invention to meter a dose at substantially lower force.

Furthermore, the stem component of the present invention can be added as a separate assembly operation after the rest of the device has been assembled. This results in the possibility of a range of different stem sizes, defining different metering volumes being available based on an otherwise standard device. Thus the manufacturer can easily produce a range of product variants with different nominal dose sizes.

A further advantage of the one example of the valve of the present invention is that

a range of dose volumes can be selected by the user by appropriate orientation of the stem.

Examples of the present invention will now be discussed with reference to the accompanying drawings in which:

5 Figure 1a illustrates a section side view of an inhaler device according to the present invention;

Figure 1b illustrates a section side view of a valve mechanism according to the present invention;

10 Figure 2 illustrates the detail of the valve mechanism when the cap is closed, the so-called home position;

Figure 3 shows the position of the valve mechanism during metering;

Figure 4 shows the valve mechanism in the armed position;

Figure 5 shows the valve mechanism as the trigger mechanism fires;

15 Figure 6 is a schematic front view of a trigger mechanism used in conjunction with the present invention.

Figures 7a to 7c are schematic side views of the trigger mechanism in various phases of operation; and

Figure 8 shows a radial seal comprising the state of the art;

20 Figures 9a to 9c show a variant of the valve mechanism in which the user can select between two dose sizes;

Figure 10 shows a variant of the valve mechanism in which the user can select from a continuously variable range of dose sizes.

25 Figure 1 illustrates an inhaler 10 in its normal, at rest, position. The inhaler includes a pressurised container 11 having an inner valve 12. Attached to the rim 13 of the container 11 is a housing 14 within which is contained a metering chamber 15 which incorporates part of an outer valve 16. The metering chamber 15 includes a stem 17 that allows the actuation of the inner valve 12.

30 The seal of the inner valve 12 includes a valve seat 27 and a valve member 28, which has a shaft 29 and an annular flange 30 to form a T-shape in cross-section. The seal is an annular rubber seal 31 disposed between the underside of the flange 30 and the valve seat 27 of the pressurised container 11. In this manner the seal is made primarily by the pressure of the fluid in the container 11 on the top surface of the flange 30 and by the action of the return spring 32, which is retained by a cage 34. Thus, as the rubber relaxes over time the seal of the present invention will retain its integrity for longer
35 than a radial seal.

Figures 2 to 5 show the operation of the valve mechanism of the present invention. Figure 2 shows the valve mechanism in its at rest position when the cap of the inhaler is

closed. The inhaler remains in this position whenever it is not in use. The metering chamber 15 is empty and both the inner valve 12 and the outer valve 16 are closed. The outer valve 16 is a standard radial seal shuttle valve. The stem 17 is not in contact with the inner valve 12. The advantage of using a standard radial seal shuttle valve is that the pressure in the metering chamber assists the delivery of a dose and reduces the additional force required. The resulting low force to fire could not be achieved using two connected radial seals as this would result in a pathway from the metering chamber back into the canister being opened at the same time as the outer valve opening to the outside world to dispense a dose. The action of these two valves results in an interlock system that prevents the two valves from ever being opened simultaneously.

Metering of a dose of medicament is initiated by the opening of the cap of the inhaler. The position of the various components at this point in the operation of the device are shown in Figure 3. This results in the stem 17 being pushed into contact with the inner valve 12. This in turn moves into the pressurised container 11 and allows medicament to flow from the pressurised container 11 into the metering chamber 15.

Figure 4 shows the armed position with the cap fully open. The stem 17 is lowered onto the trigger mechanism (not shown) and the inner valve 12 between the metering chamber 15 and pressurised container 11 is closed. The pressure of the medicament in the metering chamber 15 forces the stem 17 down against the trigger mechanism (not shown)

In this example of the present invention the valve seal 33 of the outer valve 16 is provided by a separate rubber component in the form of an O-ring. However, in other examples it may be advantageous to use a lip seal that is an integral part of the stem 17.

Figure 5 shows a dose being dispensed. The trigger mechanism fires allowing the stem 17 to drop as a result of the pressure in the metering chamber 15. The radial seal 33 of the valve 16 passes the exit hole 18 and the dose is delivered.

Figure 6 shows a schematic front view of the trigger mechanism in its armed position. This position occurs as a result of pressure in the metering chamber 15 pushing the stem 17 down on a top pivot 19. The top pivot 19 cannot move down as the middle pivot 20 is in contact with the end stop 21. Activation by the user's breath causes air to flow past flap 22 and rotate it in an anti-clockwise direction.

Figure 7a also shows the trigger mechanism in its armed position. In Figure 7b the trigger mechanism is shown moving towards the fired position. This occurs as a result of the through flow of air past the flap 22 that moves the middle pivot 20 away from the end stop 21. The middle pivot 20 first passes the point where all pivots are co-linear. Once this point has been passed the top pivot 19 can move down allowing the stem 17 to extend out of the metering chamber 15 and fire a dose of medicament. The lower flap

22 rotates anti-clockwise until it is stopped by the flap stop 23. This position is illustrated in Figure 7c. To reset the trigger mechanism the flap 22 is rotated clockwise. In one example of the present invention this is performed by closing the cap of the mouthpiece. As the cap is closed the flap 22 is returned to the armed position shown in Figure 7a with the middle pivot 20 against the end stop 21.

The dimensions of the valve mechanism may be chosen so that either the stem 17 may pop out as a result of the pressure on the stem 17, or alternatively must be pulled out against the friction in the outer seal 33.

In the former configuration the stem diameter is around 3mm. The typical frictional force with an O-ring seal is approximately 1.0 N. Typically the pressure in an inhaler aerosol is between 4 and 5 bars. The stem will by default pop out and fire the dose when the metering chamber 15 fills. This can be used with the trigger mechanism illustrated in Figure 7.

In the second variant the stem 17 is physically attached to the top pivot 19. This allows the linkage to pull the stem 17 down as the flap 22 rotates in an anti-clockwise direction.

Figure 8 shows a radial seal common in the art. It consists of a rubber seal 26 surrounding the stem 17 and as the stem 17 is lifted to open the valve, the one end 24 of the bore 25 passes the seal 26 and allows medicament to flow through the bore 25 and leave the inhaler device.

In one variant of the design a range of dose volumes can be selected by the user by appropriate orientation of the stem. Figure 9a shows a variant of the stem with a castellation feature on the top surface. An isometric view of this feature is shown in figure 9b. There is an identical feature on the shaft 29 of the valve member 28. In one orientation of the stem, shown in figure 9a, these features interlock. In another orientation of the stem, shown in figure 9c, these features butt up against each other. This latter configuration increases the effective length and volume of the metering chamber and hence the dose size that will be dispensed.

There are many end shapes for the stem 17 that would allow the dose size to be determined by the orientation of the stem. Figure 10 gives an illustration of another possible arrangement.

CLAIMS

1. A valve mechanism for use in an inhaler comprising a pressurised container and a metering chamber, the valve mechanism comprising:
 - 5 a first valve member arranged to be positioned between the pressurised container and the metering chamber, the first valve member being movable between a closed position in which the container is closed, and an open position in which the container is open to the metering chamber, the first valve member being biased to remain in the first position by the pressure in the container and a return spring; and
 - 10 a second valve member movable between a rest position in which the metering chamber is closed, a metering position in which the valve member actuates the opening of the first valve member to enable a metered dose of medicament to be dispensed into the metering chamber, and an open position in which the metering chamber is open to allow medicament to be inhaled.
 - 15
2. A valve mechanism according to claim 1, wherein the second valve member includes a surface that enables the pressure in the metering chamber to assist the opening of the second valve member.
- 20 3. A valve mechanism according to claim 1 or claim 2, wherein a surface at the end of the second valve member that contacts the first valve member during metering of a dose, is a cam surface and the first valve member has a cooperating surface, whereby the dose size can be varied.
- 25 4. A valve mechanism according to claim 1 or claim 2, wherein a surface at the end of the second valve member that contacts the first valve member during metering of a dose is stepped and the first valve member has a cooperating surface, whereby the dose size can be varied.
- 30 5. A valve mechanism according to any of the preceding claims, wherein the second valve member is a radial seal, and wherein the movements of the first and second valve members are independent of one another.
6. A valve mechanism according to any of claims 3 to 5, wherein the end surface of
35 the second valve member allows the size of the dose to be adjusted.
7. A valve mechanism according to claim 1, wherein the cross-section of the first

valve member is T-shaped.

8. An inhaler mechanism incorporating a valve mechanism according to any of the preceding claims connected to a pressurised container.

ABSTRACT

5 A valve mechanism is provided for use in an inhaler comprising a pressurised container, and a metering chamber, and a valve mechanism wherein the inlet and outlet valves are separate and can be operated independently. The pressure of the fluid in the canister is used to aid the opening of the outer valve so reducing the force to fire a dose. A variant of the valve mechanism allows the user to select from a range of dose volumes by appropriate orientation of the stem.
